Aim: To study object segmentation.

Objective: Object segmentation using the Watershed and GrabCut algorithms, Example of foreground detection with GrabCut, Image segmentation with the Watershed algorithm

Theory:

- 1. Image segmentation is the process of dividing an image into several disjoint small local areas or cluster sets according to certain rules and principles. The watershed algorithm is a computer vision technique used for image region segmentation. It is an algorithm that correctly determines the "outline of an object".
- 2. The algorithm used for foreground extraction is GrabCut Algorithm. In this algorithm, the region is drawn in accordance with the foreground, and a rectangle is drawn over it. This is the rectangle that encases our main object. The region coordinates are decided over understanding the foreground mask. But this segmentation is not perfect, as it may have marked some foreground region as background and vice versa. This problem can be avoided manually. This foreground extraction technique functions just like a green screen in cinematics.
- 3. The watershed algorithm uses topographic information to divide an image into multiple segments or regions. The algorithm views an image as a topographic surface, each pixel representing a different height. The watershed algorithm uses this information to identify catchment basins, similar to how water would collect in valleys in a real topographic map.

The whole process of the watershed algorithm can be summarized in the following steps:

- Marker placement: The first step is to place markers on the local minima, or the lowest points, in the image. These markers serve as the starting points for the flooding process.
- Flooding: The algorithm then floods the image with different colors, starting from the markers. As the color spreads, it fills up the catchment basins until it reaches the boundaries of the objects or regions in the image.

Department of Computer Engineering

- Catchment basin formation: As the color spreads, the catchment basins are gradually filled, creating a segmentation of the image. The resulting segments or regions are assigned unique colors, which can then be used to identify different objects or features in the image.
- Boundary identification: The watershed algorithm uses the boundaries between the different colored regions to identify the objects or regions in the image. The resulting segmentation can be used for object recognition, image analysis, and feature extraction tasks.

Conclusion:

In conclusion, this experiment delved into the techniques of object segmentation using the Watershed and GrabCut algorithms. The Watershed algorithm effectively divided the image into distinct regions by treating it as a topographic surface, allowing for precise segmentation. Meanwhile, the GrabCut algorithm facilitated foreground extraction by initially marking the region of interest and iteratively refining the segmentation. These techniques play a crucial role in computer vision applications, enabling accurate object delineation and feature extraction for further analysis and recognition tasks.
